2026

Abstract

This report documents three distinct architectural approaches to the OpenAI Parameter Golf competition, which imposes strict constraints of 16 MB for model weights and code combined, with 10 minutes allocated for training and an additional 10 minutes for evaluation. We present Ouroboros6, a recurrent transformer achieving depth through parameter reuse with Mixture-of-Depths routing; SSM8, a state-space model with extended hidden state capacity through the "Fat State" design; and LiteFormer-11L, a standard transformer with aggressive int6 quantization and zstd-22 compression. Each architecture incorporates evaluation-time Test-Time Training (TTT) with Low-Rank Adaptation (LoRA). We provide detailed analysis of optimization techniques including Newton-Schulz orthogonalization, time-based scheduling, and memory-efficient data pipelines. Comparative results demonstrate tradeoffs between recursive depth, structured computation, and compression-aware design, with each approach showing strong potential to achieve competitive Bits Per Byte (BPB) metrics, despite empirical constraints preventing full budget compliance.

1 Introduction

This section outlines the foundational constraints of the competition, the unique challenges of the evaluation phase, and our primary architectural contributions.

1.1 Competition Constraints

The OpenAI Parameter Golf competition presents a constrained optimization problem: maximize language modeling capability within severe resource bounds. The specific constraints are:

- **Memory Budget:** 16 MB total for model weights and code combined
- **Training Time:** Exactly 10 minutes on 8× NVIDIA H100 GPUs
- **Evaluation Time:** Additional 10 minutes for test-time adaptation
- **Evaluation Metric:** Bits Per Byte (BPB) on held-out text corpora

These constraints function as a forcing mechanism for architectural innovation. Traditional approaches relying on scale and computation become infeasible, necessitating exploration of parameter efficiency, structural regularization, and aggressive compression.

1.2 The Evaluation Challenge

A critical component initially underappreciated is the evaluation phase. Standard practice evaluates models on fixed test sets with frozen weights. However, the competition permits adaptation during evaluation, leading to development of *Score-First Test-Time Training* (TTT). This methodology adapts model parameters on previously evaluated windows before predicting current tokens, subject to the constraint that evaluation never accesses future information.

1.3 Contributions

This work presents four primary contributions:

1. **Ouroboros6**: A cascaded LoopLM architecture with 6 independent transformer blocks processed through 8 recurrent iterations, incorporating Mixture-of-Depths routing for compute-efficient depth.
2. **SSM8**: A "Fat State" Mamba architecture extending the hidden state dimension to 34 (vs. standard 8-16), providing enhanced long-range memory within parameter constraints.
3. **LiteFormer-11L**: A compression-maximized transformer employing int6 quantization, GPTQ-lite threshold optimization, and zstd-22 compression to fit 35M parameters within 14.5 MB.
4. **Comprehensive Optimization Analysis**: Detailed examination of training and inference optimizations including Newton-Schulz orthogonalization, time-based scheduling, memory-efficient data pipelines, and Score-First TTT methodology.

2 Background and Related Work

Our architectural designs build upon several key advancements in parameter-efficient deep learning, spanning recurrent computation, state-space modeling, and extreme model compression.

2.1 Recurrent Transformers and LoopLM

The concept of achieving depth through parameter reuse rather than parameter count has gained attention through LoopLM [1]. The fundamental insight is that a transformer block can be applied recurrently:

$$F^{(t)}(\cdot) = \text{lmhead} \circ \underbrace{\mathcal{M}^L \circ \cdots \circ \mathcal{M}^L}_{t \text{ iterations}} \circ \text{emb}(\cdot) \tag{1}$$

Where t represents recurrent steps. This formulation connects looping to latent reasoning, where hidden states form progressive refinements [1].

The Universal Transformer [2] demonstrated that weight tying across layers reduces parameter count while maintaining expressiveness. ALBERT [3] extended this with embedding factorization, showing viable paths for edge deployment.

2.2 Mixture-of-Depths

Dynamic compute allocation through Mixture-of-Depths (MoD) [4] enables models to process only a fraction of tokens through expensive MLP layers. The routing mechanism selects top-k tokens by learned importance scores:

$$\text{topk_indices} = \text{topk}(\sigma(W_r \cdot x), k) \tag{2}$$

This reduces computation while maintaining depth, crucial for parameter-constrained scenarios.

2.3 State Space Models

State Space Models (SSMs) [5] provide linear-time sequence modeling through structured state transitions. The Mamba architecture [6] introduces selective scanning, enabling input-dependent state transitions while maintaining efficiency.

The continuous-time formulation:

$$\dot{x}(t) = A \cdot x(t) + B \cdot u(t) \tag{3}$$

$$y(t) = C \cdot x(t) + D \cdot u(t) \tag{4}$$

discretizes (via Euler approximation) to:

$$x_k = \bar{A} \cdot x_{k-1} + \bar{B} \cdot u_k \tag{5}$$

$$y_k = C \cdot x_k + D \cdot u_k \tag{6}$$

where $\bar{A} = \exp(\Delta t \cdot A)$ and $\bar{B} = \Delta t \cdot B$.

HiPPO initialization [7] provides theoretically optimal state matrices for history compression via Legendre polynomial projection.

2.4 Model Compression and Quantization

Quantization-aware training enables models to maintain performance at reduced precision. GPTQ [8] demonstrates post-training quantization through optimal clipping threshold search.

KV cache compression addresses memory bottlenecks in long-context generation [9]. Grouped Query Attention (GQA) reduces cache size by sharing KV heads across query heads.

2.5 Low-Rank Adaptation

LoRA [10] enables efficient adaptation through trainable rank-decomposition matrices:

$$W = W_0 + BA \tag{7}$$

where $B \in \mathbb{R}^{d \times r}$, $A \in \mathbb{R}^{r \times k}$, and $r \ll \min(d, k)$. This reduces trainable parameters by orders of magnitude while maintaining expressiveness.

3 Methodology

In this section, we detail the implementation of our three distinct architectural models and the underlying data pipeline that supports them.

3.1 Shared Training Infrastructure

Before discussing specific model architectures, we outline the common data loading and filtering mechanisms utilized across all experiments to maximize hardware throughput.

FastGolfDataLoader. The data pipeline implements several optimizations for high-throughput training:

- **Memory-mapped I/O:** Uses `np.memmap` for zero-copy disk reads
- **Async prefetching:** Background thread continuously loads batches
- **Pinned memory:** Enables asynchronous GPU transfer via `tensor.pin_memory()`
- **Distributed striding:** Each GPU rank processes non-overlapping shards

EntropyFilter with Curriculum Learning. Data quality filtering uses zlib compression ratio as an entropy proxy. The curriculum schedule progressively tightens quality requirements:

Table 1: EntropyFilter Curriculum Schedule

Training Progress	Compression Ratio Threshold
0–20%	4.0 (permissive)
20–50%	2.5 (moderate)
50–80%	2.0 (strict)
80–100%	1.8 (high quality)

Lower ratios indicate less compressible, higher-entropy text. The filter prevents low-information samples from consuming training budget.

3.2 Ouroboros6: Cascaded LoopLM with Hexa MoD

Our first architectural approach leverages recurrent layers and conditional computation to achieve high effective depth within a minimal parameter footprint.

Architecture. Ouroboros6 consists of 6 independent transformer blocks, each processed through 8 recurrent iterations:

$$h^{(t,l)} = h^{(t,l-1)} + \text{Attention}(\text{LN}(h^{(t,l-1)})) + \text{MoD-MLP}(h^{(t,l-1)}) \tag{8}$$

Iteration embeddings provide positional information for each loop:

$$h^{(t,0)} = h^{(t-1,6)} + \text{iter_embed}(t) \tag{9}$$

Mixture-of-Depths Routing. MoD selectively processes tokens through MLP layers:

Algorithm 1 Mixture-of-Depths Routing

Require: Input $x \in \mathbb{R}^{B \times T \times d}$, capacity $c = 0.8$

$k \leftarrow \max(1, \lfloor T \cdot c \rfloor)$
$s \leftarrow \sigma(W_r \cdot x)$ ▷ Routing scores
$p, \text{idx} \leftarrow \text{topk}(s, k)$ ▷ Top-k probabilities and indices
$\text{selected} \leftarrow x[:, \text{idx}, :]$ ▷ Gather selected tokens
$m \leftarrow \text{MLP}(\text{selected})$ ▷ Process through MLP
$m \leftarrow m \cdot p$ ▷ Weight by routing probability
$\text{output} \leftarrow \text{scatter}(0, \text{idx}, m)$ ▷ Scatter back to positions

Configuration. The final hyperparameters for the Ouroboros6 model are detailed below.

Table 2: Ouroboros6 Configuration

Parameter	Value
Vocabulary Size	1056
Model Dimension (d_{model})	320
Attention Heads	5
Hidden Dimension	864
Physical Layers	6
Recurrent Iterations	8
MoD Capacity	0.8
Total Parameters	∼8M
Compressed Size	∼15.9 MB

3.3 SSM8: Fat State Mamba

Our second approach shifts from traditional attention to state-space models, utilizing a widened hidden state to improve long-range sequence modeling.

Architecture. SSM8 implements 8 Mamba blocks with extended hidden state:

$$\begin{aligned} x_k &= \bar{A} \cdot x_{k-1} + \bar{B} \cdot u_k \\ y_k &= C \cdot x_k + D \cdot u_k \end{aligned} \tag{10}$$

where the discretized matrices derive from learnable time steps Δt.

HiPPO Initialization. The state matrix A initializes via HiPPO-LegS:

$$A[i, n] = n + 1 \quad \text{for} \quad n \in [0, d_{\text{state}}) \tag{11}$$

Stored in log-space as $A_{\log} = \log(A)$ for numerical stability.

Anti-Autocast Poisoning. SSM dynamics parameters (A, D, Δt) operate in FP32 regardless of training precision. This prevents BF16 numerical errors ($\epsilon_{\text{BF16}} \approx 7.8 \times 10^{-3}$) from accumulating over 2048-token sequences.

Algorithm 2 Selective Scan with Precision Protection

```
function SelectiveScan(u, Δt, A, B, C, D, z)
    A ← −exp(A_log)                          ▷ FP32 state matrix
    u ← u.float()                            ▷ Cast input to FP32
    Δt ← Δt.float()                          ▷ Cast time steps to FP32
    return selective_scan_fn(u, Δt, A, B, C, D, z)
end function
```

Configuration. The structural definitions for the SSM8 model ensure the expanded state fits within the limits.

Table 3: SSM8 Configuration

Parameter	Value
Vocabulary Size	1056
Model Dimension (d_{model})	640
Inner Dimension (d_{inner})	1280
State Dimension (d_{state})	34
Convolution Kernel (d_{conv})	4
Layers	8
Total Parameters	∼14M
Compressed Size	∼15.5 MB

3.4 LiteFormer-11L: Compression-Maximized Transformer

Our final approach explores the limits of post-training compression, attempting to fit a relatively large standard transformer into the memory budget.

Architecture. LiteFormer-11L employs standard transformer architecture with compression-oriented modifications:

Grouped Query Attention (GQA):

$$\text{KV heads} = 4 \quad (\text{vs. } 8 \text{ query heads}) \tag{12}$$

This reduces KV cache by 50% while maintaining attention expressiveness.

relu^2 Activation:

$$\text{relu}^2(x) = (\max(0, x))^2 \tag{13}$$

Creates sparsity (many zero activations) improving compressibility.

BigramHashEmbedding:

$$\text{bucket} = (\text{prev_token} \cdot V + \text{curr_token}) \mod 2048 \tag{14}$$

Captures local token-pair statistics with minimal parameters ($2048 \times 128 + 128 \times 512 = 327,680$).

Compression Pipeline. The three-stage compression process:

1. **int6 Quantization:** Per-row scaling to $[-31, 31]$

$$q = \text{round}(w/s) \quad \text{where} \quad s = \max|w|/31 \tag{15}$$

2. **GPTQ-lite:** Optimal clipping threshold search across percentiles $[0.999, 0.9995, 0.9999, 0.99995, 1.0]$
3. **zstd-22:** Lossless compression achieving 15–20% additional reduction

Configuration and Compression Reality. Theoretically, int6 quantization followed by zstd-22 compression should achieve 14.5 MB for 35M parameters. However, empirical evaluation revealed the actual compressed size exceeded the 16 MB budget.

Table 4: LiteFormer-11L Configuration and Compression Results

Parameter	**Value**
Vocabulary Size	1056
Model Dimension (d_{model})	512
Query Heads	8
KV Heads	4
Hidden Dimension	1536
Layers	11
XSA Layers	4 (last layers)
Total Parameters	∼35M
Expected int6 Size	∼27 MB
Expected zstd-22 Size	∼14.5 MB
Actual Compressed Size	∼20.13 MB

Why Compression Failed: Weight distributions exhibited higher entropy than anticipated. The relu^2 activation created sparsity, but outlier values in attention projections reduced zstd compression efficiency. This discrepancy between theoretical and empirical compression explains why LiteFormer-11L was not selected for final submission despite its architectural merits.

4 Optimization Techniques

To effectively train these models within the strict 10-minute constraint, we implemented several mathematical and system-level optimizations.

4.1 Muon Optimizer with Newton-Schulz

The Muon optimizer implements momentum with 5-step Newton-Schulz orthogonalization:

Algorithm 3 Newton-Schulz 5-Step Iteration

Require: Gradient matrix G, coefficients $(a, b, c) = (3.4445, -4.7750, 2.0315)$

```
X ← G/||G||
if X.shape[0] > X.shape[1] then
    X ← X^T                                   ▷ Transpose if needed
end if
for i = 1 to 5 do
    A ← X · X^T
    B ← b · A + c · A · A
    X ← a · X + B · X
end for
if transposed then
    X ← X^T
end if
return X
```

Coefficients (a, b, c) derive from convergence analysis [11]. Scale correction by aspect ratio ensures stable updates across different matrix shapes.

4.2 Time-Based WSD Scheduler

Traditional step-based scheduling fails under variable compilation times and hardware fluctuations. The WSD (Warmup-Stable-Decay) scheduler operates on elapsed time:

$$\mathrm{lr}(t) = \begin{cases} \mathrm{max_lr} \cdot \frac{t}{t_{\text{warmup}}} & t < t_{\text{warmup}} \\ \mathrm{max_lr} & t_{\text{warmup}} \leq t < t_{\text{stable}} \\ \mathrm{min_lr} + (\mathrm{max_lr} - \mathrm{min_lr}) \cdot \frac{1+\cos(\pi \cdot \frac{t - t_{\text{stable}}}{t_{\text{decay}}})}{2} & t \geq t_{\text{stable}} \end{cases} \tag{16}$$

Phases: 10% warmup, 70% stable, 20% cosine decay.

4.3 Memory Optimizations

Beyond algorithmic improvements, structural changes to the standard transformer blocks were necessary to reduce activation memory and parameter counts.

RMSNorm. Root Mean Square normalization avoids mean centering:

$$\mathrm{RMSNorm}(x) = \frac{x}{\sqrt{\frac{1}{d}\sum_{i=1}^{d} x_i^2 + \epsilon}} \cdot \gamma \tag{17}$$

More efficient than LayerNorm while maintaining training stability.

Fused QKV Projection. Single linear layer projects to Q, K, V simultaneously:

$$\mathrm{QKV} = W_{\text{fused}} \cdot x \quad \in \mathbb{R}^{d_{\text{model}} \times 3d_{\text{model}}} \tag{18}$$

Reduces memory accesses by 3× vs. separate projections.

Weight Tying. Embedding matrix shared with LM head:

$$W_{\text{lm_head}} = W_{\text{embedding}}^T \tag{19}$$

Saves $V \times d$ parameters ($\sim$540K for vocab=1056, d=512).

4.4 Compilation Optimizations

`torch.compile` with `mode="max-autotune"` provides 20–30% throughput improvement after warmup. Critical exclusions via `@torch.compiler.disable` prevent compilation of CUDA kernels (selective_scan_fn) that cannot be traced by Inductor.

TF32 tensor cores enabled via `torch.backends.cuda.matmul.allow_tf32 = True` accelerate matrix multiplications with minimal precision loss on H100 GPUs.

5 Evaluation Methodology

The evaluation phase of the competition requires careful management of context windows and metric calculations to optimize the final score within the time limits.

5.1 Score-First Test-Time Training

The evaluation phase employs Score-First TTT, where LoRA adapters train on previous context windows before predicting current windows. This maintains validity: evaluation never accesses future information. The number of TTT steps per window is strictly bounded to ensure the entire process completes within the 10-minute evaluation constraint.

Algorithm 4 Score-First TTT Evaluation

Require: Model M, LoRA injector $\mathcal{L}$, optimizer $\mathcal{O}$

```
1:  L.inject(M)                                   ▷ Inject LoRA adapters
2:  prev_X, prev_Y ← None, None
3:  for each window W_i in validation data do
4:      if prev_X is not None then
5:                                                ▷ TTT on previous window
6:          for step = 1 to TTT_STEPS do
7:              O.zero_grad()
8:              Ŷ ← M(prev_X)                     ▷ Forward pass
9:              L ← CrossEntropy(Ŷ, prev_Y)       ▷ Compute loss
10:             L.backward()                      ▷ Backpropagate
11:             O.step()                          ▷ Update LoRA only
12:         end for
13:     end if
14:                                               ▷ Evaluate current window
15:     X_i, Y_i ← W_i
16:     Ŷ_i ← M(X_i)                              ▷ No gradient
17:     accumulate_metrics(Ŷ_i, Y_i)
18:     prev_X, prev_Y ← X_i, Y_i
19: end for
```

5.2 Bits Per Byte Calculation

The competition metric is Bits Per Byte (BPB):

$$\text{BPB} = \frac{\text{NLL}/\ln(2)}{\text{total_bytes}} \tag{20}$$

where NLL is negative log-likelihood and total_bytes accounts for actual UTF-8 encoding lengths. A byte-length LUT precomputes per-token byte counts for accurate accounting.

5.3 Sliding Window Strategy

Table 5: Sliding Window Configuration

Model	Sequence Length	Stride
Ouroboros6, LiteFormer-11L	2048	64
SSM8	2048	256

SSM8 uses larger stride due to native long-range memory via state caching. Transformers use smaller stride for maximum context utilization.

6 Results and Analysis

We evaluate the three architectures based on their parameter efficiency, empirical compression limits, and relative design tradeoffs.

6.1 Parameter Budget Utilization

Table 6: Parameter and Memory Budgets

Model	Params	BF16	Exp. Compressed	Actual	Budget
Ouroboros6	∼8M	∼16.0 MB	∼15.9 MB	15.9 MB	99.4%
SSM8	∼14M	∼28.0 MB	∼15.5 MB	15.5 MB	96.9%
LiteFormer-11L	∼35M	∼70.0 MB	∼14.5 MB	**20.13 MB**	**FAIL**

Note: LiteFormer-11L exceeded the 16 MB budget despite theoretical projections of 14.5 MB. Consequently, LiteFormer-11L was not selected for final submission, though it demonstrated competitive BPB metrics during evaluation.

6.2 Ablation: Ouroboros Depth

To determine the optimal configuration for Ouroboros6, ablation studies were conducted locally using a 5-minute proxy training run on a downloaded subset of the competition dataset. This duration proved sufficient to identify early convergence patterns and representation bottlenecks.

Table 7: Effect of Layer Count in Ouroboros

Layers	Loss	Notes
1	2.919	Insufficient depth
2	2.603	Improving
4	2.484	Good
6	2.432	Optimal
8	2.560	Representation bottleneck

The 8-layer configuration suffers from reduced $d_{\text{model}} = 256$, demonstrating that width matters as much as depth.

6.3 Design Philosophy Comparison

- **Ouroboros6**: Depth through recurrence, parameter efficient, limited parallelism
- **SSM8**: Efficiency through structure, linear complexity, kernel dependency
- **LiteFormer-11L**: Capacity through compression, maximum parameters, quantization noise

Each achieves competitive BPB within the 16 MB constraint through distinct mechanisms.

7 Retrospective

Looking back at the development process, we identify key methodological successes and note approaches that ultimately proved unsuccessful.

Time-based control eliminated step sensitivity. Curriculum learning progressively improved data quality. Newton-Schulz orthogonalization stabilized deep recurrent training. Score-First TTT provided meaningful evaluation-time adaptation.

Ouroboros8 with $d_{\text{model}} = 256$ exhibited representation bottlenecks. Initial attempts at byte-level tokenization proved incompatible with competition data. Step-based scheduling failed under JIT compilation variability.

This work represents the author's first AI engineering project. The iterative development—from naive initial attempts to increasingly sophisticated solutions—demonstrates the learning process inherent in experimental research. Each architecture embodies lessons from previous failures, documented honestly herein.

8 Conclusion

In this report, we presented three distinct architectural paradigms to address the severe constraints of the OpenAI Parameter Golf competition: Ouroboros6 utilizing compute-efficient recurrent depth, SSM8 leveraging structured state spaces with expanded memory capacity, and LiteFormer-11L exploring the absolute limits of post-training compression.

While Ouroboros6 and SSM8 successfully operated within the strict 16 MB boundary and demonstrated competitive Bits Per Byte (BPB) performance, the empirical compression limits encountered by LiteFormer-11L highlighted the practical barriers of high-entropy weight distributions in heavily quantized transformers. Furthermore, we established that architectural design alone is insufficient under such extreme conditions. System-level optimizations—specifically time-based learning rate scheduling, Newton-Schulz orthogonalization, and our Score-First Test-Time Training (TTT) methodology—proved critical for maximizing performance within the unyielding 10-minute training and evaluation windows.

Ultimately, this work demonstrates that severe parameter constraints necessitate a departure from traditional scaling laws in favor of structural reuse and dynamic computation. Future work may explore hybrid architectures combining the parameter-sharing efficiency of looped models with the linear-time sequence processing of state-space representations.
